Abstract

Drug reaction with eosinophilia and systemic symptoms (DRESS) and drug-induced liver injury (DILI) can hamper therapeutic strategy, contribute to multiple drug resistance and serious public health burden. Diagnosis (including allergy assessment) and management of these two severe hypersensitivity reactions in clinical practice are somewhat difficult and published scientific evidence is rather weak and limited. The first step is always represented by stopping all anti-tuberculosis (TB) drugs, treating reaction with systemic corticosteroids, and identifying the offending drug, even if it is often complicated by the patient’s simultaneous intake of antibiotics. Patch tests and in vitro tests, such as lymphocyte transformation test, could bridge this diagnostic gap, but the available data are scarce and their sensitivity low. The re-challenge test is often necessary but places patients at risk for serious adverse reactions. The desensitization protocols are quite varied and not universally accepted. In this narrative review, we provide an update to the literature data on the management of DRESS and DILI with particular attention to the allergological work-up in the last decade.

Key words: Antituberculosis drugs, systemic severe reactions, Drug Reaction with Eosinophilia and Systemic Symptoms, drug-induced hypersensitivity syndrome, Drug-Induced Liver Injury, T-cell-mediated hypersensitivity, allergological management, re-challenge, desensitization
This review reports an update from the last decade on severe systemic hypersensitivity reactions to anti-TB drugs with particular emphasis on allergological management.

Methods

In order to describe the most recent reports of severe non-blistering systemic reactions (DRESS, DIHS, DILI) induced by anti-tuberculosis drugs, a review of literature was carried out. PubMed and Web of science were searched up from 2012 to September 2022.

Primary screening was performed using the following MeSH headings and keywords: “antitubercular agents”, “antitubercular drugs”, “anti-tuberculosis agents”, “anti-tuberculosis drugs” and “antibiotics, antitubercular”. Secondary screening was performed using terms such as “drug hypersensitivity syndrome”, “drug reaction with eosinophilia and systemic symptoms syndrome”, “DRESS syndrome” and “chemical and drug induced liver injury”.

Criteria for inclusion were as follows: full-text case reports, classical articles, clinical studies, letters, and observational studies available online. Criteria for exclusion were as follows: duplicate publications, unavailability of full-text, language other than English, and review articles.

From each report, we retrieved data regarding time of onset of clinical manifestations, culprit drug and allergological diagnostic tests (skin prick test (SPTs), intradermal tests (IDTs), patch tests, lymphocyte transformation tests (LTTs)).

Results

I. DRESS and antitubercular drugs

DRESS or drug-induced hypersensitivity syndrome (DIHS) is a potential life-threatening severe adverse drug reaction characterized by an extensive skin rash in association with visceral organ involvement, lymphadenopathy, eosinophilia and other hematological abnormalities. The latency between drug exposure and the disease onset is generally between 2-8 weeks. The incidence of DRESS is estimated between 1 in 1000 and 1 in 10,000 drug administrations with a mortality rate of up to 10%. The diagnosis of DRESS is performed usually following European Registry of Severe Cutaneous Adverse Reactions to Drugs and Collection of Biological Samples (RegiSCAR) group criteria.

RegiSCAR criteria let to classified patients with suspected DRESS into definite, probable, possible or no cases, based on following characteristics: 1) skin eruption, 2) fever (>38°C), 3) lymphadenopathy at least 2 sites, 4) involvement of at least 1 internal organ, 5) lymphocytosis (> 4 x 10^3/μL) or lymphocytopenia (< 1.5 x 10^3/μL), 6) blood eosinophilia (> 10% or 700/μL), and 7) thrombocytopenia (< 120 x 10^3/μL). Mizukawa et al. have developed a scale useful to evaluate the severity of DRESS based on the collection of clinical and anamnestic data. This scale includes fixed and variable parameters that ranges from -1 to 3. When the drug responsible for the reaction is allopurinol, 1 starting point is assigned, as this is recognized as a risk factor for severe disease and renal failure.

The incidence...
The clinical history of allopurinol intake before and during the onset of the manifestations is considered a risk factor (1 point). Score < 1 describes mild disease, in this case therapy is not required. Scores between 1 and 3 describe moderate disease. Finally, levels ≥ 4 describe severe disease. This latter condition requires a high-dose corticosteroid therapy. Based on the compound score proposed by Mizukawa et al. The final score, resulting from this scale, allows to assess the disease severity and to drive therapeutic strategies, since it represents a useful indicator of therapeutic response.

The pathogenesis of DRESS is multifactorial and not deeply understood, probably due to an interaction among genetic and environmental factors such as a genetic deficiency of detoxifying enzyme, human leukocyte antigen (HLA) haplotypes predisposing, virus–drug interactions (HHV-6). However, the pathogenesis involves a delayed type hypersensitivity reaction, where T-helper type 2 cells play an important role.

In the skin and involved organ, biopsies reveal CD4+ and CD8+ T cells, responsible for the production of Th2 proinflammatory cytokines and chemokines such as thymus and activation-regulated chemokine (TARC) and macrophage-derived chemokine (MDC).

Innate immunity is also involved. In fact, IL-5 secreting innate lymphoid cell 2 (ILC2s) are involved in the immunopathogenesis of DRESS favoring the recruitment and activation of eosinophils. The increase in TNF-α and INF-γ levels suggest an overlap with the Th1 pattern. Furthermore, in the early stages of DRESS, there is an expansion of the Tregs with consequent state of Treg-mediated immunosuppression, responsible for the reactivation of the herpes viruses (Figure 2).

The most frequent involved culprit drugs include anticonvulsant, allopurinol, antibiotics, and antiretroviral drugs. Antitubercular drugs are uncommonly reported cause of DRESS, probably underdiagnosed or delay diagnosed. Most DRESS reactions described in literature occurred during first line (FL) anti-TB drugs (rifampicin, isoniazid, pyrazinamide, and ethambutol) (Table 1). In a case-control pharmacogenetic study, HLA Cw*0401 is reported as possible risk factor for antitubercular-associated DRESS development. DRESS syndrome onset during antitubercular treatment represents a serious complication may lead to therapy discontinuation, high-dose of systemic corticosteroids use and second-line therapy.

### 1.1 Culprit antitubercular drugs

Among antitubercular drugs, rifampicin is most involved drug following by isoniazid in development of DRESS though often the patients undergo an antibiotics combination protocol, and the identification of culprit drug is difficult to realize. Analyzing French pharmacovigilance database, Allouchery et al. reported the largest series of antitubercular drug-associated DRESS describing 67 cases. They recorded rifampicin and isoniazid as the most involved drugs with a median time of symptoms onset of 24 days of treatment.
Figure 2. A genetic predisposition and some acquired factors, such as herpes virus infections or a reduced drug metabolism, are involved in the development of DRESS. In these patients, the administration of specific pharmacological classes could induce the activation of T cells (CD4 and CD8), ILC2, and Tregs. Tregs could favor the reactivation of herpes viruses.\textsuperscript{14-16}

In their case series, a drug allergy evaluation was performed in 11 patients (10 patch test and 1 intradermal/prick test with delayed readings) and was positive in 8 cases. Two patients died from DRESS. Overall, rifampicin seems to be the most suspected because of its larger indications while isoniazid is associated with a deeper allergy investigation that indicated it as culprit drug,\textsuperscript{19} less cases are related to ethambutol,\textsuperscript{20} none with pyrazinamide alone.

A recent large Turkish study\textsuperscript{21} found a global prevalence of drug hypersensitivity reactions to antituberculosis drugs of 7.8%. About a third of patients developed Type IV hypersensitivity reactions, most frequently represented by maculopapular eruption. Rifampicin was the most frequently responsible drug for developing Type IV hypersensitivity reactions, followed by pyrazinamide, isoniazid, and ethambutol.

Identification of culprit drug is often complicate in clinical practice by the possibility of a multiple drug hypersensitivity (MDH) in these patients.

DRESS is the severe cutaneous adverse reaction most frequently associated with MDH, which can be presented up to 18% of cases of DRESS.\textsuperscript{22} The most accredited hypothesis sees transient immunosuppression and the costimulatory signals provided by viral reactivation and/or sensitization to the first drug as cofactors capable of increasing the stimulation of an immune response to other drugs and leading to the development of hypersensitivity to different classes of medications.\textsuperscript{22}

In this regard, Toujani et al.\textsuperscript{23} attempted a rechallenge with a separate and sequential reintroduction of the involved drugs (HRZE) with positive results for all of them. Systemic symptoms reappeared with each reintroduction and the time to onset of symptoms was variable (3-7 days).

Carneiro-Leão L et al.\textsuperscript{24} demonstrated a MDH in patient treated in the 15 last days, at first with piperacillin/tazobactam and vancomycin for community-acquired pneumonia and then with HRZE for tuberculosis infection. In this case,

1. Time of onset symptoms (days)
2. ATDs = anti tuberculosis drugs; SPT = skin prick test; IDT = intradermal test; LTT = lymphocyte transformation test; DS = desensitization; HRZE = isoniazid/rifampicin/ethambutol/para-aminosalicylic acid; Eth = ethionamide; Mfx = moxifloxacin; PAS = para-aminosalicylic acid; Lvx = levofloxacin; Z = pyrazinamide; S = streptomycin; Km = kanamycin; Cs = cycloserin; MDHS = multiple-drug hypersensitivity syndrome.

3. N° of pts = number of patients; 1st ATDs: 1st anti tuberculosis drugs; 2nd ATDs: 2nd anti tuberculosis drugs; 3rd ATDs: 3rd anti tuberculosis drugs; 4th ATDs: 4th anti tuberculosis drugs; 6/6: rifabutin to replace R; 5/6: change all drug; 3/6: change 3 drugs; 2/6: change 2 drugs; 1/6: change 1 drug;篠13 (11 pts with 1st ATDs and 2 pts with 2nd ATDs); 14: change all drug; 2-6: E performed in 9/27: multiple drug pos.

4. Evaluated number of patients with drug re-challenge
patch test resulted positive for isoniazid and lymphocyte transformation tests (LTTs) were positive to all drugs involved confirming MDH. However, on the basis on higher stimulation index for rifampicin and isoniazid rather than other anti-TB drugs, Authors readministered ethambutol and pyrazinamide without adverse effects. Furthermore, anti-TB could often be associated with other drugs known to induce DRESS (such as allopurinol) making it more difficult to identify the exact cause of DRESS. In fact, Ogawa et al.\(^\text{29}\) report a case of allopurinol-induced DRESS complicated by isoniazid hypersensitivity confirmed by patch and LTTs.

Table 1 summarizes the characteristics of the other cases reported in the literature.\(^\text{26–44}\)

### 1.2 Allergological evaluations

Identifying the culprit drug is critical to restoring effective therapy quickly and safely. Therefore, an allergological in vivo or in vitro tests may prove useful to recognize the culprit drug. Preferably, an allergological work-up should be done after at least 4-6 weeks after a complete remission of clinical manifestations of DRESS syndrome. In published cases, this time is often shortened to rapidly restore a therapy for these patients.

The diagnostic tool available does not seem to have high sensitivity and specificity and they do not often used in the clinical practice. Intradermal and skin prick tests are rarely performed and not standardized. Patch test can be useful in case of DRESS with a high specificity and a sensitivity reported between 32-64% depending on the drugs.\(^\text{35}\) Interestingly, Shebe et al.\(^\text{46}\) reported a case of systemic reaction (pruritus, eosinophilia, hepatitis, facial oedema, conjunctivitis, hemorrhagic cheilitis and erythematous tender palms) after rifampicin patch test application in a patient affected by HIV suggesting a possible life-threatening drug reactions associated with allergological evaluations in these patients.

LTTs are in vitro test helpful for the diagnosis of DRESS. LTT measures the uptake of a DNA precursor, tritiated thymidine, by lymphocytes after exposure to an antigen. Drug-induced LTT has a limited sensitivity ranging between 23-57% depending on considered drug, higher for isoniazid, but 93-98% of specificity that might aid in identifying the culprit drug.\(^\text{47}\) Ye et al.\(^\text{48}\) recorded a specific T cell response to isoniazid and rifampicin in patients with antituberculosis drug-induced DRESS syndrome or maculopapular exanthema. In their experience, LTT results agreed with oral provocation test while often were not associated with patch test results. Although LTT does not present any risk to the patient, compared to other allergy tests, and can be performed immediately after reactions, it is not routinely performed, especially in those countries where tuberculosis is currently widespread.

### 1.3 Rechallenge, retreatment and cross-reactivity

The management of anti-TB-related DRESS foresees the immediate withdrawing all drugs involved and starting topical and/or systemic corticosteroid therapy. Once clinical resolution is obtained, after 4-6 weeks, an allergological work-up is necessary to identify the culprit drugs and drive the reintroduction of other FL-anti-TB, but it is not always performed or reliable. Several Authors adopt a sequential reintroduction of FL antituberculosis drugs (e.g., one drug every 3-5 days) in increasing doses.\(^\text{49}\) Nevertheless, the exact dose escalation and the order of drugs to be readministered, as well as the use of concomitant autoreactive therapy remain heterogenous and debated. Although sometimes it can reveal as a diagnostic aid, this approach should be performed carefully because often complicated by DRESS resumption, potentially life-threatening. Second-line antituberculosis drugs, such as aminoglycosides (streptomycin, amikacin, kanamycin) and quinolones (levofloxacin, moxiﬂoxacin, ofloxacin, ciprofloxacin), can be administrated alternately or added to patients’ therapy. These drugs represent safer option but generally less effective. For these reasons, rechallenge should only be considered when the risks associated with suboptimal therapy outweigh those of a possible reaction and only in a specialized environment. Moreover, concerning the alternative treatment, although ethionamide and isoniazid have structural analogues, the risk of cross-reactivity seems low.\(^\text{50}\) Several findings also suggest the lack of cross-reactivity between rifampicin and rifabutin,\(^\text{51–53}\) but the absence of such cross-reactivity remains to be confirmed by further evidences.

### 1.4 Desensitization

Desensitization (DS) consists in a stepwise administration until reaching a therapeutic dose of culprit drug inducing a temporary tolerance and allowing the patient to complete an uninterrupted course of medication safely. The exact mechanism behind desensitization is not completely understood but it could provoke an increase of T-reg that could downregulated T-cell activated by antigen. DS is generally not recommended in serious adverse reaction following drugs administration.\(^\text{44}\) However, a desensitization protocol can be a reasonable option for patients with anti-TB drug-related DRESS to resume anti-TB medication. Antituberculosis drug desensitization data have been described in the literature.\(^\text{55–57}\) To date, the only institutional protocol, a 16-day slow desensitization protocol, proposed by the Japanese Society for Tuberculosis in 1997\(^\text{10}\) was effectively tested for the first time in nineteen patients between August 1998 and March 2000 by Kobashi Y. and coworkers.\(^\text{59}\) Furthermore, the authors highlighted correlated factor with the success, such as the longer period from the discontinuation to the desensitization therapy and lower doses of drugs at starting desensitization.\(^\text{59}\)
In the recent years, some Authors tried desensitization protocols in cases where benefit of therapy outweighed the risk of a severe reaction to procedure. These studies recorded anti-TB DS success rate of 62.5-63.6% in DRESS cases. Regarding breakthrough reactions during DS, Ban GY et al demonstrated that the drugs identified during allergological work-up showed significantly high reactions rates ($p = 0.014$), although this was not correlated with desensitization failure rate. Recently, Oh et al proposed a desensitization protocol as a safe and well-tolerated option after anti-TB DRESS, especially when there are no effective alternative drugs, compared with graded challenges or complete changing drugs regimes.

The utilization of antihistamines and corticosteroids as premedication for desensitization also remains controversial with limited evidence in literature. Scherer and colleagues reported no difference between patients who took anti-reactive therapy daily during desensitization and those who did not. Such premedication seems rather more useful for relieving allergic symptoms in patients with skin diseases or a history of adverse drug reactions.

However, further data are necessary to assess the actual safety, tolerability, and effectiveness of desensitization protocols.

2. Drug-induced liver injury (DILI) and anti-tubercular drugs

DILI is a liver disease that commonly occurs 5-90 days after drug ingestion. Its clinical spectrum ranges from only biochemical abnormalities to an acute liver insufficiency.

Traditionally, DILI is classified into intrinsic (dose-related, predictable, and short latency to onset) and idiosyncratic (not dose-related, unpredictable, and variable latency to onset). Idiosyncratic DILI (DIDL) can be sub-classified into genetically mediated IDILI and immune-mediated IDILI (that can manifest with hypersensibility or drug-induced autoimmune injury). DILI is histopathologically classified into three groups: hepatocellular, cholestatic and mixed according to the Council for International Organizations of Medical Sciences (CIOMS).

Hepatocellular damage occurs when alanine aminotransferase (ALT) is $\geq 3$ ULN (upper limit of normality) or the ratio ($R$) between ALT and alkaline phosphatase (ALP) is $\geq 5$ ($R = \text{ALT serum activity} / \text{ALP serum activity}$). Hepatocellular type injury is more severe than cholestatic or mixed types. ALP $\geq 2$ ULN or $R \leq 2$ occurs in cholestatic type injury, while mixed type is defined by ALT $\geq 3$ ULN, ALP $\geq 2$ ULN and $2 < R < 5$. Cholestatic and mixed type appear to occur more in patients with chronic disease.

Vascular liver injury is a rare histopathological alteration mainly due to radio-chemotherapy and pyrrolizidine alkaloid-based herbs (e.g., gynura segetum). From a study published in 2006 on a small population of DILI patients at a center in Singapore, anti-TB drugs appear to be the second cause after herbal medicines. It has been shown that isoniazid, rifampicin and pyrazinamide (metabolized by the liver) can cause DILI, while for ethambutol or streptomycin it has not been clearly described.

DILI due to anti-tuberculosis drugs is a diagnosis of exclusion: personal medical history, physical examination and liver biochemistry are crucial in the diagnosis while imaging and liver biopsy should be discussed based on clinical presentation. For this reason, it is difficult to establish the exact incidence. Studies have shown a variable incidence between 2% and 28%.

A study on the Chinese population found a 2.55% incidence of DILI with an asymptomatic rate of 33%; 70% of patients had to change their therapeutic regimen. In a Malaysian study of 473 TB patients, 9.7% developed hepatitis, and in a Sri Lankan study of 783 patients, the incidence was 9.5%. On the other hand, in Tanzania, the incidence is lower than expected.

A study on 47,594 patients identified a DILI incidence of 0.03% per year, and 80% of these were related to anti-TB.

Advanced age, female sex, pregnancy, malnutrition, chronic ethanol consumption appear to be the major risk factors. Furthermore, HIV infection, concomitant use of anti-retroviral drugs, decreased CD4 counts, and extrapolmonary TB infection are associated with an increased risk of developing hepatitis.

Over the years, many authors have also evaluated the possible genetic predisposition to develop liver damage with anti-TB intake. It has been hypothesized that mutations in genes involved in drug metabolism may promote liver damage. It has been known for many years that the detection of a slow NAT2 acetylation phenotype represents a significant risk factor for Isoniazid-induced toxicity. Higuchi et al. demonstrated that the frequency of a variant haplotype, NAT2 6A, was significantly increased in patients with hepatotoxicity while the frequency of a wild-type haplotype, NAT2 4, was significantly lower. These data have also been recently confirmed.

Evaluation of cytochrome P450 2E1 (CYP2E1) polymorphisms could be a useful diagnostic tool.

In 2010, Wang et al. investigated the association between the genetic polymorphism of cytochrome P450 2E1 (CYP2E1) and glutathione S-transferase mu 1 (GSTM1) with the risk of developing DILI from anti-TB therapy. Their results demonstrated that the CYP2E1 Rsal c1/c1 genotype is a risk factor for the development of DILI in these patients, while the GSTM1 Rsal null genotype appears to increase susceptibility.

DILI clinical severity is classified into five grades: from grade 0 (no liver injury) to grade 5 (death) (Table 2).
Table 2. DILI clinical severity grading.

2.1. Isoniazid

Isoniazid inhibits the formation of the mycobacterial cell wall. It is cleared mainly by the liver and its hepatotoxicity appears to be idiosyncratic and caused by its toxic metabolites. The hepatic enzyme N-acetyltransferase 2 (NAT2) metabolizes the majority of isoniazid into acetylisoniazid and only a small part of isoniazid is hydrolyzed into isonicotinic acid and hydrazine; this pathway seems to be predominant in slow acetylators, which develop hepatic injury more often and more severely than fast acetylators. This behaviour suggests hydrazine and its toxic metabolites (acylated hydrazine, hydrazones and nitrogen gas) hepatotoxicity. CYP 2E1 c1/c1 genotype increases CYP 2E1 activity and appears to be involved to a higher hepatotoxins production.

Bhatia et al. described a case of recurrent DILI in a child treated with isoniazid and rifampicin. Isoniazid has been defined as responsible for pruritus episodes of liver damage, and according to the authors, in cases of recurrent DILI, fluoroquinolones may be preferred. According to Branco Caetano et al., the hepatotoxic effect of isoniazid would be enhanced by anti-epileptic therapy and the ketogenic diet. The author reported two cases of DILI in patients diagnosed with epilepsy undergoing anti-TB treatment.

2.2 Rifampicin

Rifampicin can rarely induce a dose-dependent hepatotoxicity due to an interference with bilirubin uptake, causing an unconjugated hyperbilirubinemia by inhibiting the bile salt exporter pump.

2.3 Pyrazinamide

The mechanism of pyrazinamide hepatotoxicity is unknown. Since pyrazinamide is only used in combination therapy, its toxicity is unclear to date. In 2001, the Centers for Disease Control and Prevention (CDC) reported two episodes of severe hepatitis associated with the combination of rifampin and pyrazinamide in New York and Georgia.

Wang et al. reported the case of a 78-year-old man with biopsy-confirmed liver injury secondary to pyrazinamide therapy. Upon suspension of the therapy, the liver damage regressed, and a new cycle with ethambutol and levofloxacin was started. The patient had a NAT2 slow acetylator phenotype, which may be implicated in pyrazinamide toxicity by unknown mechanisms.

Ruslami et al. reported 4 cases of pyrazinamide-related hepatotoxicity.

2.4 Ethambutol and streptomycin

To date, no hepatotoxicity is described.

2.5 Management

One in five patients shows an increase in serum transaminase levels when treated with standard anti-TBC regimen and resolves spontaneously. Routine transaminase monitoring is unnecessary if no risk factors or underlying liver disease coexist. Some authors suggest monitoring liver function in the first eight weeks of treatment in patients treated with anti-TB. British Thoracic Society (BTS) suggest monitoring liver function only of patients with known chronic liver disease for the first 2 months.
American Thoracic Society (ATS) guidelines suggest a baseline liver function testing in at risk patients. If hepatotoxicity occurs, after stopping the treatment, ATS guidelines suggests restarting anti-TBC drugs one at a time." For BTS, in the case of DILI, the treatment must be suspended, and once liver function normalizes, the drugs can be reintroduced sequentially in the order: isoniazid, rifampicin, pyrazinamide; these patients should be monitored daily for clinical condition and liver function. In 2014, Zuberi et al. compared the two main guidelines for the treatment of tuberculosis. According to the authors, there are no substantial differences in the treatment of DILI between the ATS and BTS guidelines. Sharma et al. evaluated with good results the reintroduction of the three main drugs (isoniazid, rifampicin, and ethambutol) simultaneously and at full dosage, with advantages on patients with bilateral pulmonary tuberculosis or for life-threatening patients.

There is no evidence on correct approaches for reintroducing anti-TB therapy in pediatric patients with comorbidities (meningitis, HIV infection, cardiac disease), and standardized guidelines would be needed.

2.6 What literature adds about the diagnostic evaluation?

According to the most recent studies, the dosage of bilirubin, the MELD score, creatinine, albumin, and INR can be markers of the severity of liver damage. According to some authors, these markers and signs of encephalopathy, ascites, and jaundice are associated with poor prognoses.

Hepatitis B and cirrhosis are important risk factors, and the Child-Pugh score should be evaluated before starting treatment.

There are conflicting results in the literature. Saha et al. found no statistically significant risk factors. Given the high incidence of DILI in patients on anti-TB therapy, according to Abbara et al., it would be helpful to monitor liver damage enzymes in the first eight weeks of treatment.

Cao et al. evaluating urinary metabolites, found that tricarboxylic acid circulation, arginine and proline metabolism and purine metabolic pathways were affected by anti-tuberculosis treatment. Potential diagnostic markers such as mean eosinophilic volume (MEV) and mean eosinophilic volume and size variability (MEV-SD) were described by Shen et al. Changes in serum values of these biomarkers were present in patients who had undergone antituberculosis therapy. To date, no allergy tests are reported in the literature to correctly diagnose or predict drug-induced liver injury due to ADTs. The only diagnostic procedure also described by the current guidelines provides for the suspension and subsequent reintroduction of the drugs involved.

Some authors have tried to associate traditional therapeutic schemes with supplements capable of reducing hepatotoxicity. Good results were obtained with silymarin, with a mix of medicinal herbs and cholecalciferol.

Table 3 summarizes the main studies in the literature on DILI induced by anti-TB drugs. Due to the lack of clinical studies in the last decade, we have also included studies from previous years. Further data collection is needed to strengthen the evidence.

Conclusions

The World Health Organization Global Tuberculosis Report 2021 defines tuberculosis as the second infectious disease that causes sickness and death after SARS-CoV-2 infection and ranks it as the 13th among the global causes of death. To date, the prevalence of the patients developing a hypersensitivity reaction against antituberculosis drugs is yet unknown. Patients should stop their antituberculosis treatment if any hypersensitivity reaction occurs against any of the drugs used. This situation not only delays the treatment but also represents a diagnostic and therapeutic challenge for clinician. Furthermore, adverse effects of the medication, in particular severe hypersensitivity reactions not properly managed, will also disrupt the patient’s compliance with treatment and will weigh heavily on health care costs, requiring admission or prolongation of existing admission. Known risk factors for adverse drug reactions are: genetic factors (some HLA sequences), women’s lower body weight, advanced age, smaller organ sizes, greater body fat, gastric motility differences, and lower glomerular filtration rate, neo-diagnosis versus previous anti-tuberculosis treatment. The most common agents responsible for hypersensitivity reactions are rifampicin, isoniazid, and ethambutol. More and more frequent is the finding of multiple sensitivities against antituberculosis drugs. The first step of the management of a hypersensitivity reaction is the interruption of suspected culprit drug, followed by antihistamine treatment, steroid treatment, or their combinations. The next challenge for the clinician is identifying the drug responsible for hypersensitivity reaction before drug reintroduction. Current diagnostic difficulties include: the limited availability of intravenous preparations for intradermal testing and the need for cutaneous manifestation recovery before testing. For ex vivo testing [such as IFN-gamma release enzyme-linked immunospot (ELISpot) assay], which can be a problem in low-income countries.

In the spirit of nurturing research, overcoming roadblocks, and innovating the practice, eHealth technologies could be a way to enhance diagnosis procedures at each step of the management of patients with tuberculosis. Through eHealth, the development of adverse reactions to antituberculosis drugs could be early intercepted with desirable reduction of morbidity and mortality. The Authors believe that future research should focus on: 1) diagnostic pathways based on clinical risk stratification and dual strategy involving sequential challenge and rapid drug desensitization, 2) definition and constant up-date of well-phenotyped cohorts in order to uncover genomic predictors of hypersensitivity reactions. Finally, a concerted international effort is needed to generate real-time data on hypersensitivity reactions to antituberculosis drugs. This global and multidisciplinary approach will improve the compliance of the patients to the antituberculosis treatment.

Key messages

- Anti-tuberculosis drugs may be responsible for severe delayed hypersensitivity reactions (DRESS and DILI).
- The main drugs involved are rifampicin, isoniazid, and ethambutol.
- These drugs are often administered in combination; this approach potentially complicates the diagnostic work-up.
- Skin prick and intradermal tests are not conclusive. Patch tests with suspect drugs and lymphocyte transformation tests (LTTs) can be useful tools for diagnostic work-up, although sensitivity and specificity vary from drug to drug.
- A multidisciplinary approach, greater awareness of data collection and the search for standardized diagnostic tests are necessary pillars to ensure a correct diagnosis and a better compliance of the patient.

Conflicts of Interest

The authors declare no conflict of interest.
